Texts Don't Nudge: An Adaptive Trial to Prevent the Spread of COVID-19 in India

Girija Bahety, Sebastian Bauhoff, Dev Patel, and James Potter

Abstract

We conduct an adaptive randomized controlled trial to evaluate the impact of a SMS-based information campaign on the adoption of social distancing and handwashing in rural Bihar, India, six months into the COVID-19 pandemic. We test 10 arms that vary in delivery timing and message framing, changing content to highlight gains or losses for either one's own family or community. We identify the optimal treatment separately for each targeted behavior by adaptively allocating shares across arms over 10 experimental rounds using exploration sampling (Kasy and Sautmann, 2021). Based on phone surveys with nearly 4,000 households and using several elicitation methods, we do not find evidence of impact on knowledge or adoption of preventive health behavior, and our confidence intervals cannot rule out positive effects as large as 5.5 percentage points, or 16 percent. Our results suggest that SMS-based information campaigns may have limited efficacy after the initial phase of a pandemic.

1 Introduction

Preventive behaviors such as handwashing and social distancing are critical to containing the spread of infectious diseases like COVID-19, particularly in densely populated areas of developing countries with crowded living quarters and public spaces. As a pandemic unfolds, identifying ways to encourage the adoption of protective health behaviors in a timely, efficient, and cost-effective way is critical for public health (Van Bavel et al., 2020).

We examine the impact of text messages (or Short Message Service, SMS) on preventive health behavior through a multi-arm iterative randomized-controlled trial in rural India. Using a sample of phone numbers from birth registers at health centers in Saran district in the state of Bihar, we randomly sent some individuals four text messages over the course of two days. We ran two experiments in parallel during the first peak of the country's COVID-19 pandemic, between 17 August and 20 October 2020, one encouraging handwashing and other social distancing. For each outcome—handwashing and social distancing—we test 10 treatment arms that vary across two dimensions that could influence treatment effectiveness: message frame and delivery timing. Informed by research in public health, psychology and behavioral economics, we consider five variants of message framing, changing content to highlight public gain or loss, private gain or loss, or neutral. We also varied the time of day when the messages were sent: either twice in the morning (7:00-8:00 a.m. and 10:00-11:00 a.m.) or once in the morning and once in the evening (7:00-8:00 a.m. and 6:00-7:00 p.m.).

Testing these large number of arms lends itself to an adaptive trial approach to efficiently recover the best policy. Following the exploration sampling algorithm of Kasy and Sautmann (2021), we reallocated treatment shares over the course of 10 rounds to identify the combination of timing and message framing that is most effective. We conducted phone surveys with recipients three days after the first message was sent, along with surveys of control households who did not receive any messages. To mitigate concerns about experimenter demand, we measured preventive health behaviors first through an open-ended question and then via direct elicitation and a list experiment. We conduct both randomization statistical inference and inference using standard asymptotic approaches. For a sub-sample, we conducted phone surveys five days after the first message was sent to check for decay in treatment effects.

We find no evidence that any of our SMS-based information campaigns improve knowledge or adoption of social distancing and handwashing. This is true across several elicitation methods designed to address concerns of experimenter demand. We cannot, however, reject potentially meaningful treatment effects: Looking at all arms together for each target behavior, our confidence intervals allow us to reject direct impacts of 5.5 percentage points (p.p.)

off of a control mean of 36% for adopting social distancing, and 5.6 p.p. off a base of 35% for adopting handwashing. We also find no evidence of indirect effects, e.g., of handwashing messages on social distancing behaviors, nor evidence of heterogeneous treatment effects by timing of the experiment round, literacy and recall period, although our estimates for such impacts are imprecise.

Our study makes several contributions: First, our results are particularly policy-relevant to the new waves in COVID-19 in Spring 2021 which occur after extensive awareness about the disease. Second, our study builds on a growing number of studies in economics using adaptive approaches to allocate treatment shares in an experimental settings (Caria et al., 2020; Kasy and Teytelboym, 2020a, 2020b). We implement what is to the best of our knowledge, one of the first applications of the exploration sampling approach of (Kasy and Sautmann, 2021). Third, we contribute to a rich literature that has tested the potential for nudges and information to improve health behavior (e.g., Alatas et al., 2020; Bennear et al., 2013; Dupas, 2009; Madajewicz et al., 2007; Meredith et al., 2013). Fourth, we also add to research on optimal message framing by cross-randomizing gain or loss message framing with public or private framing and comparing it with a neutral message to understand their marginal impacts. Much of the evidence on information campaigns during COVID-19 from developed countries shows mixed results regarding the importance of these specific design features of messages (Jordan et al., 2020; Favero and Pedersen, 2020; Falco and Zaccagni, 2020). Fifth, we also examine whether the delivery timing impacts the efficacy of information or nudges (Kasy and Sautmann, 2021).

Finally, our study also adds to recent research using phone-based information campaigns to encourage preventive health behavior for COVID-19 in South Asia. Banerjee et al. (2020) randomly sent video links to households in West Bengal in May 2020 and measure both the direct and spillover effects, on respondents who directly received the link or may have learned about it through their networks. They document large positive overall impacts on social distancing, handwashing, and hygiene behaviors. Our confidence intervals on handwashing include their point estimates. They do not find private or public gain framed messages to have differential effects and do not find impacts on knowledge of symptoms or precautions. In another study in Uttar Pradesh and Bangladesh in April 2020, Siddique et al. (2020) find significant impacts on both COVID-19 knowledge and behavior from phone calls plus sending messages and phone calls alone relative to just sending SMS. Armand et al. (2021) randomly sent a WhatsApp video or audio recordings of messages from doctors to the urban poor in Uttar Pradesh and find decreased probabilities of leaving the slum area but no effects on handwashing. In rural Bangladesh, Chowdhury et al. (2020) find that information campaigns on social distancing and hygiene measures improved preventive behaviors.

There are several potential explanations for the lack of impacts in our study. First, our study takes place several months into the pandemic, at a time when cases were spiking and after households across India had received COVID-19 messages and endured lockdowns for several months. At this stage, households may have already been well-informed or too fatigued to respond; they may also have faced higher opportunity costs of adopting preventive behaviors like social distancing after the prolonged economic disruption of the pandemic. Second, our intervention featured relatively plain SMS, without any celebrity or professional endorsements nor the video or audio components of other studies. Text messages are accessible even on basic phones, potentially expanding access in the context of only 24% smartphone penetration in India (Rajagopalan and Tabarrok, 2020) but require literacy and may be relatively less engaging (Favero and Pedersen, 2020). Third, we focus on a different elicitation approach to measure compliance with health behavior. To reduce risk of experimenter demand, we asked respondents to list all actions they are taking to protect against the virus. By contrast, (Siddique et al., 2020) directly ask respondents if they wash their hands or maintain distance. We do elicit second-order beliefs on community behaviors like in (Banerjee et al., 2020) but find no evidence of treatment effects on reported community-level social distancing and handwashing in our experiment. Fourth, while (Banerjee et al., 2020) randomize across communities, our experiment varied treatment at the individual level. If there are significant spillovers from our treatment like in (Banerjee et al., 2020), they will attenuate our point estimates.

The remainder of this paper proceeds as follows: Section 2 describes the setting of the experiment, study sample, intervention, the adaptive trial design, and primary data collection. Section 3 describes the empirical strategy and main results, and Section 4 discusses implications for health messaging campaigns, especially in the context of pandemics.

2 Study Context and Design

As of August 17, 2020, India had recorded a cumulative total of 2.7 million confirmed COVID-19 cases (Roser et al., 2020) and true infection rates were an order of magnitude higher (Mohanan et al., 2021). We conducted our study in collaboration with the Bihar state government and Suvita during the initial height of the country's pandemic between August 17 and October 20, 2020. The experiment took place in Saran, a rural district in the western part of Bihar that resembles the state's overall socio-economic characteristics and pandemic experience.[1] New cases increased in early July and peaked in early August, just before

---

[1]The study design was pre-registered at the AEA Registry as AEARCTR-0005780 but for two additional health behaviors, a smaller sample size, and in the state of Maharashtra. We changed the study location

our study started (Appendix Figure B.1). Bihar imposed a full lockdown in mid-July and maintained a partial lockdown in August that remained effective during the first three weeks of our trial. Throughout the pandemic, public service announcements advocating hygiene and social distancing were widely distributed via television, radio, newspapers, and text messages. Although cell phone ownership is almost universal among households in Bihar, this may overstate the potential scope for SMS campaigns: according to the 2011 census, just 67% of women and 82% of men in Saran were literate.

Study Sample   Our sample was recruited from a list of households who entered phone numbers into birth registries at health centers in 15 out of 20 blocks in Saran between August 2019 and February 2020.[2] We randomly selected phone numbers within four strata based on block characteristics from the 2011 Census: above and below average literacy rate and above and below average proportion of Scheduled Castes and Scheduled Tribes (SC/ST) population.

Table 1 shows the summary statistics and balance across treatment and control groups for key demographic characteristics in Panel A, SMS-related information in Panel B, and knowledge of symptoms and access to health care in Panel C. About three-quarters of the respondents were male with an average age of 31 years. Less than a third of the sample was unemployed, and most of those who worked did so in a manual job. Eighty-six percent of respondents can read SMS in Hindi, but 36% do not ever read text messages. Less than a third read SMS daily in the week prior to the interview. Knowledge of COVID-19 symptoms and practice of ante-natal care is balanced across treatment and control.

Intervention Design   Our trial compares 10 message types varying in framing and timing to target social distancing and handwashing. Each treated phone number was sent four text messages in Hindi over the course of two days. We chose five different message frames based on principles from psychology and behavioral economics (Tversky and Kahneman, 1979, 1991; Van Bavel et al., 2020): neutral, public gain or loss, and private gain or loss. These message frames may appeal to different emotions, such as fear (by making the threat of pandemic salient) or prosocial motivation (by highlighting externalities of the preventive actions). Appendix A shows the different messages by content framing for each behavior. The neutral messages give simple, directed advice: For social distancing, the neutral message states "Coronavirus is here. Outside the house, keep a distance of at least two arms from

and number of behaviors in response to local conditions, but all remaining aspects of the pre-registration still apply.

[2]According to the 2019-2020 National Family Health Survey (NFHS-5), 75% of births in rural Bihar take place at a health facility.

others." For handwashing, the neutral message is "Coronavirus is here. Before touching any food or touching your face, wash your hands with water and soap." In the public loss arms, appealing to both fear and prosocial motivation, the first sentence is replaced with "Coronavirus kills. Your action can put your community at risk of infection." In the public gain arms, the first sentence is instead replaced with "Save lives. Your action can protect your community from coronavirus." The private gain and loss arms are the same as the public gain or loss arms, except "community" is replaced with "family."

The delivery timing can impact the efficacy of information or nudges (Kasy and Sautmann, 2021). To explore this issue, we vary the time of day when messages were sent across treatment arms. In all arms, the first message was sent between 7:00 and 8:00 a.m. in the morning. In twice-morning arms, a second SMS was sent between 10:00 and 11:00 a.m., while in morning-evening arms, the second message was sent between 6:00 and 7:00 p.m. The rationale for selection of these timings was to ensure nudges were delivered either at the start of the day or later in the evening. We create 10 treatment arms using each of the five framings for both delivery timings.

Experimental Design We randomly assigned our sample to 10 rounds of treatment for each behavior. We implemented the "exploration sampling" procedure from Kasy and Sautmann (2021) to allocate sample to the different treatment arms over the course of the experiment. An adaptive approach is particularly appealing in this setting because it provides more statistical power in identifying optimal treatment over a large set of alternatives. The "exploration sampling" method uses a modified Thompson sampling procedure to iterate over the different messaging campaign attributes to identify those that are most effective in shaping reported behavior. In each phase of the experiment t, the probability that a unit is assigned to arm j is given by q_t^j, as defined in equation 1, where p_t^j is the posterior probability that arm j is optimal given outcomes up through period $t-1$.

$$q_t^j = \frac{p_t^j \cdot \left(1 - p_t^j\right)}{\sum_j p_t^j \cdot \left(1 - p_t^j\right)} \tag{1}$$

While traditional Thompson sampling procedures weight by p_t^j, this modification shifts weight towards the close competitors of the best performing arms. Indeed, exploration sampling is equivalent to Thompson sampling if the same treatment assignment is never assigned twice in a row. The key advantage of exploration sampling is that it achieves the best possible exponential rate of convergence subject to the constraint that in the limit, half of observations are assigned to the best treatment, thereby converging much faster than Thompson sampling or non-adaptive assignment. We used open-ended reported practice of

either social distancing or handwashing as our main outcome for the corresponding target behavior to adapt shares. Although we intended to begin with equal priors across all arms (and therefore equal shares), due to an initial coding mistake, allocations were not matched to the correct arms when the messages were sent for the first several weeks. Because this allocation mistake assigned arms shares orthogonal to their performance and the experiment continued for 10 subsequent rounds, we do not expect this to influence our findings, but effectively the priors were not equivalent across treatments. By round 6, the treatment shares became relatively stable, suggesting that we did conclude the trial with robust results.

Table 1 shows that the treatment and control groups are balanced on most demographic characteristics. The treatment group has more women, more unemployed respondents, and fewer households identifying as Other Backward Classes and Hindu. The bottom panel of the table shows that the joint test of significance for these covariates are not statistically significant. However, we control for gender, occupation, education, and age fixed effects in all specifications.

Data Collection Three days after the first text message was sent, a team of enumerators called respondents over the phone.[3] If the phone number was not answered, then the enumerators repeatedly redialled after the full list was tried once. We find no evidence of differential response rates by treatment status (p-value = 0.567 for social distancing and 0.627 for handwashing). A random subset of phone numbers were called five days later instead of three to test for potential decay effects. We staggered the phone surveys for control, social distancing and handwashing samples to facilitate the updating of the treatment shares over the frequent iterations. Out of a total of 12,799 phone numbers called, we had a response rate of 34.7%, of which 8.9% did not consent to the interview and 0.62% were under age of 18 and excluded from the sample. Of 3,964 eligible respondents who consented, 91.6% of respondents answered key outcome questions, and 74.9% completed all questions in the survey. We use all available answers for our analyses.[4] The survey covered basic respondent and household characteristics, phone usage behavior, risk perceptions, and knowledge and action regarding COVID-19 prevention.

Given concerns about experimenter demand, we elicited key preventive health behaviors using an open-ended (unprompted) question: "What are you doing to protect against the virus?". We classify compliance with social distancing and handwashing based on whether

---

[3]There were public/national holidays on August 21, September 17 and October 2. We did not send SMS on holidays and the day before and made no calls on holiday and the following two days.

[4]We made an average of 1.4 attempts per number, ranging from 1 to 8 attempts. Out of the phone numbers from which we did not get a response, 24% did not pick up despite multiple attempts, 22% were either unreachable or switched off and 17% were invalid numbers. The median completed interview lasted 17 minutes.

the respondent mentions each practice, respectively, and use this indicator to guide our adaptive trial.[5] We also elicited knowledge about preventive measures with a similar open-ended question. The order of the knowledge and practice questions was randomized across the respondents. We subsequently directly asked respondents whether they practice social distancing and handwashing.[6] We also conducted a list experiment to measure uptake of behaviors sensitive to social desirability bias by bundling (or veiling) the sensitive questions with two other innocuous statements (Chuang et al., 2020; Jamison et al., 2013; Karlan and Zinman, 2012). We asked respondents how many actions they did in the past two days: watching TV, speaking on the phone, and either social distancing or handwashing. Finally, we administered a randomly selected subset of three questions from the 13 statements in the Marlowe-Crowne Scale Social Desirability Scale (Form C) which assesses correlates to social desirability bias on measured self-reported outcomes (Crowne and Marlowe, 1960; Reynolds, 1982; Dhar et al., 2018). We used a subset of the full scale to reduce the survey length.

3   Empirical Strategy and Results

We estimate treatment effects with the ordinary least squares specification shown in equation 2:

$$Y_i = \alpha_i + \beta T_i + \gamma O_i + \mathbf{X}_i'\lambda + \varepsilon_i \tag{2}$$

where Y_i is the outcome for individual i, T_i indicates treatment for the target behavior (either social distancing or handwashing), O_i indicates treatment for the other behavior, and $\mathbf{X}_i$ is a vector of fixed effects including gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. Our results are robust to regressions specifications without any controls or with only strata fixed effects. We include both treatment groups in all specifications: for each *target* outcome or behavior—social distancing and handwashing—we include a separate treatment indicator for those who were treated for the *other* behavior (Muralidharan et al., 2019). This allows us to test for evidence of "attention" substitution—being reminded about one behavior takes attention away from another—or substitution

---

[5]For distancing, we use keeping two arms distance from others. For handwashing, we include both washing hands with water and washing hands with soap regularly as the main outcome.

[6]The prompted question for distancing asks "Have you come into close contact with anyone not in your household, that is within 2 arms distance or less? For example, when you went to meet someone in a group or for a meeting, get-together, or to go to the market or shopping." The corresponding question for handwashing asks "Have you washed hands with soap and running water, or used hand sanitizer?" Appendix C compares our definitions of outcomes to those used in related studies.

in health practices—if social distancing more makes people feel like handwashing is less necessary, for instance. We use the same control group across both targeted behaviors. Unless otherwise noted, we conduct analysis on the sample of survey respondents who were reached three days after the first message was sent for the treatment group or reached on the first day they were called for the control group.

Sample averages in adaptive trials are typically biased (Hadad et al., 2019), but under exploration sampling, this bias is negligible in large samples because assignment shares of sub-optimal treatments are bounded away from zero (Kasy and Sautmann, 2021). Thus, as long as the law of large numbers and central limit theorem apply, we can run standard t-tests ignoring the adaptivity. Because some of our treatment shares end up being quite small for some arms, in addition to asymptotic standard errors that are robust to heteroskedasticity, we also report exact p-values from randomization inference. This inference approach is particularly appealing in heterogeneous treatment effect specifications that can be vulnerable to high leverage observations given the asymmetric treatment shares (Young, 2019). To conduct the randomization inference, we randomly allocate treatment status holding constant the observed distribution of outcomes. We recreate the full adaptive trial data-generating process to create the synthetic treatment allocations. Holding constant the initial strata, we randomly re-assign the initial treatment shares and then re-run the Bayesian process to generate future shares for each round. We do not adjust for multiple hypothesis testing, as our estimates are mostly not statistically significant even without this adjustment.

First-Stage   We assess implementation fidelity by assessing whether the treatment message was delivered to the targeted recipients, as shown in Panel B of Table 1. Beginning on August 24th, 2020, a week after the experiment began, we received reports from the telecommunications provider on whether the message was delivered to the recipients' phones. Within the treatment group, on average, 72% of the respondents successfully received at least 1 message. On average and unconditional on receiving any SMS, the treatment group received 2.7 messages out of a total of four messages that were sent. Non-delivery and partial deliveries are likely due to phones being switched off or service interruptions. Almost all respondents in the treatment and control groups stated that they trusted the information in messages related to the Coronavirus.

We also compare treatment compliance by assessing self-reported measures of whether the respondent received any COVID-related SMS in the week prior to the survey and, conditional on having received any SMS, the number of SMS received and their recall of message content (Table 2). Column 1 shows that treated respondents were 28.6 p.p. more likely to report receiving any SMS related to COVID-19 in the previous week, off a base of 16% in

the control group. Column 2 shows the treatment group on the number of COVID-related messages is about one. Treated households who received handwashing messages are 21 p.p. more likely to remember that specific guidance relative to control households who also received COVID content, as shown in column 6. The comparable effects for social distancing are noisier but still positive (13.6 p.p.), as shown in column 4. These results are consistent with our finding in Panel B of Table 1 where more than a third of the respondents across the treatment and control groups did not read any SMS at all in the week prior to the survey. For comparison, Banerjee et al. (2020) found an average viewing rate of 1.14% for their YouTube videos, while Armand et al. (2021) estimate that respondents on average listened to 19-23% of WhatsApp messages.

Treatment Effects on Primary Outcomes   Overall, we find no evidence that sending SMS increased uptake of social distancing and handwashing. First, we show results for treatment arms pooled together for each targeted behavior in Figure B.2 (results also shown in Table 3). Looking at social distancing in the top panel of the figure, the observed treatment effects on both knowledge and uptake of social distancing are small, negative (a decrease in 0.2 and 0.3 p.p., off of a control mean of 49% and 36%, respectively), and not statistically significant based on asymptotic or randomization exact p-values. Similarly for handwashing in the bottom panel of the figure, the treatment effect on knowledge is 3.4 p.p. off of a control mean of 32%. The impact on uptake of handwashing is 0.2 p.p. off of a control mean of 35%. Both are statistically insignificant across both inference methods. Our 95% asymptotic confidence intervals are large enough such that we cannot rule out direct effects as large as 5.5 p.p. for each of our main behaviors. We find no evidence of indirect effects of the social distancing treatment on handwashing outcomes or vice versa. Using the randomized treatment assignment as an instrument, we find no evidence of positive treatment effects for either behavior, as shown in Table B.1. This is true both when using administrative delivery reports on text message receipt as the endogenous variable in a treatment-on-the-treated specification or self-reported receipt of any COVID-related message, suggesting that even among the "compliers" who did receive and recall the SMS, the content had no impact on preventive measures.

We evaluate the treatment effects by pooling treatment arms within the five frames in Table B.2 and within delivery timings in Table B.3. We find no systematic evidence of any impact of different framings or timings on behavior. Table B.4 presents treatment effects separately for each of the 10 treatment arms and shows no consistent effects. The few statistically significant point estimates across these specifications are likely due to chance.

9

Optimal Message Design Taken together, the previous set of results suggests no consistent or compelling evidence that a particular framing or timing was especially effective in increasing preventive health behavior. The few statistically significant effects we document are largely not replicated for the other behavior and could simply be the artifact of statistical noise. We can more formally explore the optimal message design using the insights from the adaptive procedure. Comparing each of our treatment arms against one another, we calculate the posterior probability p^j that each arm is optimal. Despite the lack of treatment effects, the exploration sampling approach did converge towards a small number of specific framings and timings as shown in Figure B.4. We present the posterior probabilities in Table 5. For social distancing, the private gain framing messages sent once in the morning and once in the evening were optimal with probability 0.575. For handwashing, the public gain messages sent twice in the morning were optimal with probability 0.431. Disaggregating the treatment effect regressions from equation 2 by 10 treatment arms in Table B.4, the treatment effects suggest that relative to the control mean of 36% for social distancing and 35% for handwashing, these arms stand out with statistically significant treatment effects among other modifications of the messages. Overall, the results do not highlight a clear recommendation for a single SMS design for other campaigns.[7]

Experimenter Demand Effects One challenge in measuring preventive health behavior in this setting is experimenter demand: respondents may report practicing social distancing or handwashing simply because they are aware they are expected to be doing so. For this reason, our primary outcomes use responses to the unprompted elicitation of behaviors or practices respondents are taking to prevent COVID-19, based on the idea that if people are not directly asked whether they are practicing a behavior, their answers will be more accurate.

To explore these issues, we compare our preferred measure to alternative elicitation approaches in Table 4. Within each behavior, the first two columns show effects on the open-ended question (our preferred outcome) and the direct elicitation measure. The third column presents outcomes from our list elicitation, in which we embedded the behavior of interest with additional statements about whether the respondent watched television yesterday or talked to a relative on the phone yesterday. Respondents answered how many of the statements (out of three) applied to them. Following Banerjee et al. (2020), the fourth column reports impacts on second-order beliefs of a typical community member's practice of social distancing and handwashing. For social distancing, we also report whether the

---

[7]This is true even before implementing potential adjustments to account for the Winner's curse in this type of experiment (Andrews et al., 2021; Banerjee et al., 2021).

respondent was with non-household members or at any other house other than her or his own at the time of the interview in columns 5 and 6.

Across all of these measures, there is no evidence of treatment effects. In Panel A, we evaluate the results for different measures for each of the outcomes by pooling treatment arms by targeted behavior. In Panel B of Table 4, we test for treatment effect heterogeneity by a measure of social desirability bias using the Marlowe-Crowne scale. Because we only elicited a random subset of the full set of items for each respondent, we estimate a 1-parameter item response theory (IRT) model to aggregate across individuals onto a common scale and use this measure for heterogeneity analysis. The intuition behind this test is that if respondents report practicing the behavior because they believe that is what the enumerator wants to hear, then we should observe stronger treatment effects among those with a greater latent propensity to desire social approval. In our analysis, we find no systematic evidence of differential effects along this margin.[8]

Heterogeneity and Spillovers We explore three further dimensions of heterogeneity. First, we examine whether our treatment effects varied over the course of the study by dividing the experiment duration into three periods of approximately four weeks. Given that the exploration sampling was not correctly implemented in the first weeks of our experiment, we create three approximately equal groups by classifying the first round as the early period and compare treatment effects over middle rounds (rounds 2 to 5) and later rounds (rounds 6 to 10) in Table B.5. We do not find any evidence of differing treatment effects by periods of the experiment, though this is difficult to interpret because the disease prevalence is changing over these months. Second, low SMS-literacy could also attenuate treatment effects in Table B.6; about 86% of our respondents can read SMS in Hindi (Table 1). We see no strong evidence that our treatments were more effective among this population, though the point estimates for handwashing are large and noisy. Third, we test for treatment effects on the 18.2% of our sample who were randomly assigned to be interviewed five days after the first message. As shown in Table B.7, we find some evidence of decay of any potential baseline treatment effect: relative to those interviewed three days after receiving the first handwashing message, those surveyed five days later are about six percentage points less likely to report washing their hands. The point estimates are close to zero for social distancing.

Additionally, we evaluate the effects of social distancing and handwashing outcomes on wearing protective masks and respiratory hygiene (covering mouth and nose while coughing or sneezing) in Table B.8 and find null effects for both the outcomes. We also check for

---

[8]We do find statistically significant heterogeneous treatment effects in the list elicitation for social distancing, but this is difficult to attribute to experiment demand because of the additional statements.

differences in risk perceptions of getting sick from or dying of COVID-19 and do not see any statistically significant differences between treatment and control group participants (Figure B.3). This suggests that the SMS did not cause people to become particularly more concerned about COVID-19 through increasing the salience of the disease.

4 Discussion

During a pandemic, effective communication is critical to encourage the take-up of preventive health behaviors that can help slow the spread of infections (Van Bavel et al., 2020). This is especially important in densely populated areas of developing countries with crowded living quarters and public spaces, and weak health systems.

We examine whether SMS-based information campaigns can be effective at encouraging the adoption of social distancing and handwashing, two key behaviors in preventing the spread of COVID-19. In our setting of rural Bihar, India, treatment participants are about 2.8 times (28.6 pp) more likely to receive a SMS related to COVID-19 than the control group. However, this first-stage does not translate into any meaningful impact on knowledge or uptake of social distancing and handwashing behavior. Based on estimated confidence intervals, we cannot rule out increases as large as 5.5 - 5.6 p.p. for knowledge and adoption of social distancing and 8.8 and 5.6 p.p. for handwashing knowledge and practice, respectively. Our main results are not directly comparable to those of similar experiments conducted during the COVID-19 pandemic in India. These studies work with different populations and only used direct elicitation (see Appendix C for a detailed comparison). Our point estimates for prompted questions are statistically insignificant and at most 0.4 p.p. for always maintaining two arms distance and 0.7 p.p. for washing hands. (Banerjee et al., 2020) find that the combined direct and spillover effects of their video intervention decreased travel outside of villages by 7.4 p.p. (20%) and no significant effect on socially distanced interactions; they also find no statistically significant effects among the relatively small sample of respondents who were directly targeted by the experiment. (Siddique et al., 2020) find that phone calls and phone calls paired with SMS increased knowledge of preventive behaviors by 53 p.p. (28%) and 85 p.p. (45%), respectively. Reported handwashing and avoiding contact increased by 80-95 p.p. compared to very low compliance in the control group that received only SMS. In terms of second order beliefs about typical community member complying with handwashing, we find an increase of 2.2 p.p. (3% increase relative to control mean) relative to 4.7 p.p. (7%) in (Banerjee et al., 2020).

There are several substantive explanations for our null findings. First, our study takes place during an advanced stage of the pandemic when citizens might already be well-informed

or too fatigued to respond to nudges. Indeed, in a small number of qualitative interviews we conducted toward the end of the study period, respondents indicated that they had been exposed to many information campaigns and had stopped abiding by these advisories. Similarly, participants may experience higher opportunity costs of adopting certain preventive behaviors, especially social distancing, after the prolonged economic disruption. Second, the majority of study participants do not have high or very high risk perception of getting infected or dying from COVID-19. This may reduce their responsiveness to our information campaign. Third, SMS may not be a sufficiently engaging medium to deliver information (Favero and Pedersen, 2020). In contrast to text messages, speaking with a real person (Siddique et al., 2020) or watching a video featuring a well-known person (Banerjee et al., 2020) appear to be effective at changing behaviors. More generally, many of our respondents do not read SMS on a daily basis. Finally, although most respondents indicated that they can read SMS in Hindi, literacy rates in our study area are low. Other modes of communication, such as phone calls, may be more appropriate and effective for this population (Siddique et al., 2020).

Overall, information campaigns based on text messages have low marginal costs and potential to scale but may be ineffective at encouraging preventive behaviors, at least after the initial stage of a pandemic. Other approaches may have more impact and, ultimately, be more cost-effective.

Control Mean	0.16	0.68	0.27	0.19	0.09	0.13
F-statistic	118.43	58.10	0.38	2.17	5.86	12.41

Note: Table 2 shows the first stage results for four self-reported measures of receipt of any COVID-related SMS: any SMS, number of SMS received in Column 1 and 2, recall of social distancing in Column 3 and 4 and handwashing messages in Column 5 and 6, respectively. The last four measures are conditional on receiving any COVID-related SMS. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. Robust standard errors in parentheses. Asymptotic p-values are denoted by: * p<0.1; ** p<0.05; *** p<0.001.

Table 3: ITT Results by Pooled Treatment

N	2,937	2,892	1,359	2,934	2,937	2,206	2,937	2,935	1,569	1,939
Control Mean	0.36	0.55	1.16	1.86	0.41	0.40	0.35	0.86	1.40	0.76

Note: Table 4 shows the results for heterogeneity analysis for social distancing and handwashing outcomes by social desirability score (SDS) measured through IRT. Panel A shows the results for ITT regressions without any interaction term on a sample with non-missing data on SDS score and Panel B shows the results for ITT regressions with the interaction terms. The ITT regression for Panel B would be: $Y_i = \alpha_i + \beta_1 T_i + \beta_2 O_i + \beta_3 SDS_i + \beta_4 T_i \times SDS_i + \beta_2 O_i \times SDS_i + \mathbf{X}'_i \lambda + \varepsilon_i$. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. The first six columns show the results for six social distancing outcomes: main, directly asked, measured through the list experiment, respondent reporting that they are with other people and at other peoples home at the time of the interview and respondent's perception of social distancing by a typical community member, respectively. The last four columns show the results for four handwashing outcomes: main, directly asked, measured through the list experiment and respondent's perception of handwashing by a typical community member, respectively. Robust standard errors are in parentheses and Fisher exact p-values are in square brackets. Asymptotic p-values are denoted by: * p<0.1; ** p<0.05; *** p<0.001.

Table 5: Summary Statistics by Treatment Arm

Note: Table 5 presents summary statistics by treatment arm. Column 1 denotes the target behavior. Column 2 denotes the framing of the message. Column 3 denotes the timing of when the SMS were sent. Column 4 lists the total number of treated respondents who were reached in a phone survey. Column 5 (μ_j) shows the mean outcome for each arm, and Column 6 (σ_j) presents the standard deviation. Column 7 (p^j) lists the posterior probability that each arm is the optimal arm at the conclusion of the experiment.

A SMS Content by Message Framing and Targeted Behavior

Table A.1: SMS Text Script

Framing	Handwashing	Distancing
Neutral	Coronavirus is here. Before touching any food or touching your face, wash your hands with water and soap.	Coronavirus is here. Outside the house, keep a distance of at least two arms from others.
Public Loss	Coronavirus kills. Your action can put our community at risk of infection. Before touching any food or touching your face, wash your hands with water and soap.	Coronavirus kills. Your action can put our community at risk of infection. Outside the house, keep a distance of at least two arms from others.
Private Loss	Coronavirus kills. Your action can put your family at risk of infection. Before touching any food or touching your face, wash your hands with water and soap.	Coronavirus kills. Your action can put your family at risk of infection. Outside the house, keep a distance of at least two arms from others.
Public Gain	Save lives. Your action can protect our community from coronavirus. Before touching any food or touching your face, wash your hands with water and soap.	Save lives. Your action can protect our community from coronavirus. Outside the house, keep a distance of at least two arms from others.
Private Gain	Save lives. Your action can protect your family from coronavirus. Before touching any food or touching your face, wash your hands with water and soap.	Save lives. Your action can protect your family from coronavirus. Outside the house, keep a distance of at least two arms from others.

Note: All messages were sent from the sender id "SEHATx", with no signature.

B   Additional Figures and Tables

Figure B.1: Average Newly Confirmed Cases per Day (per 100,000)
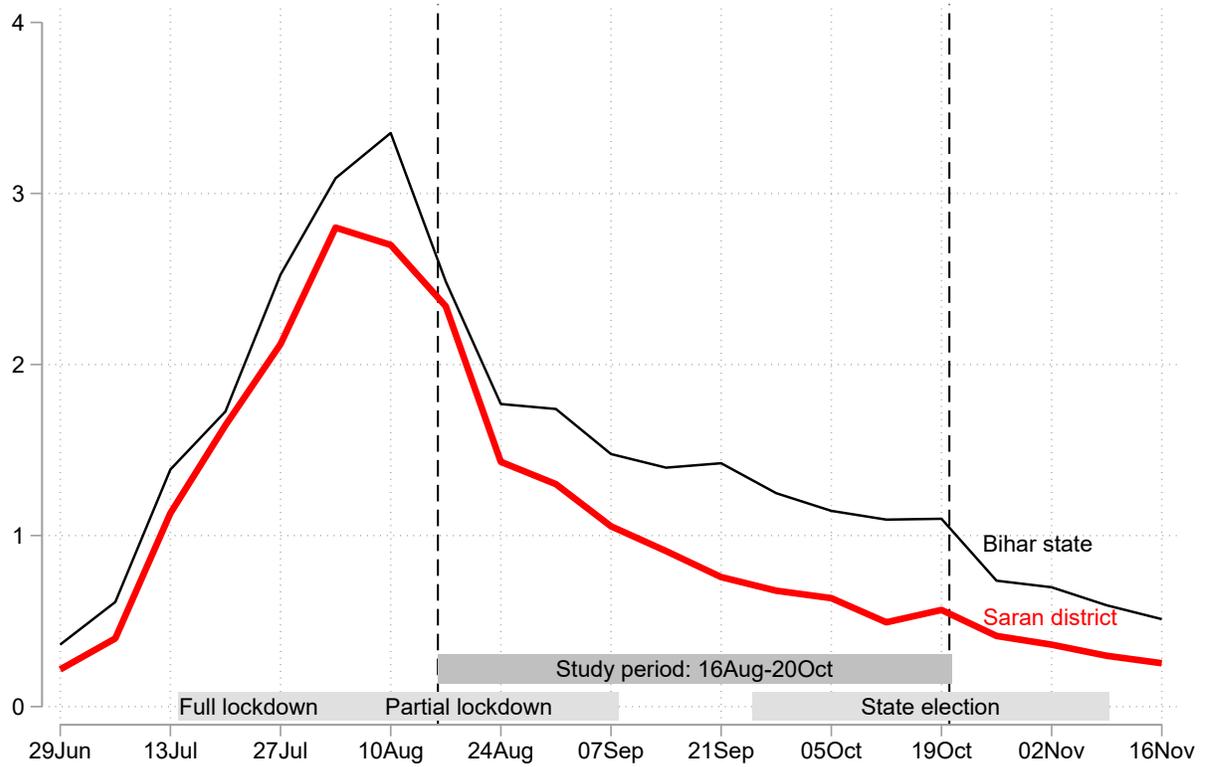

Note: Figure B.1 plots the average by calendar week of newly confirmed cases per day, per 100,000 population. Bihar was also affected by flooding in July, 2020. Source: COVID-19 India Org Data Operations Group (2020) using data collected by volunteers.

Figure B.2: Treatment Effects by Target Behavior
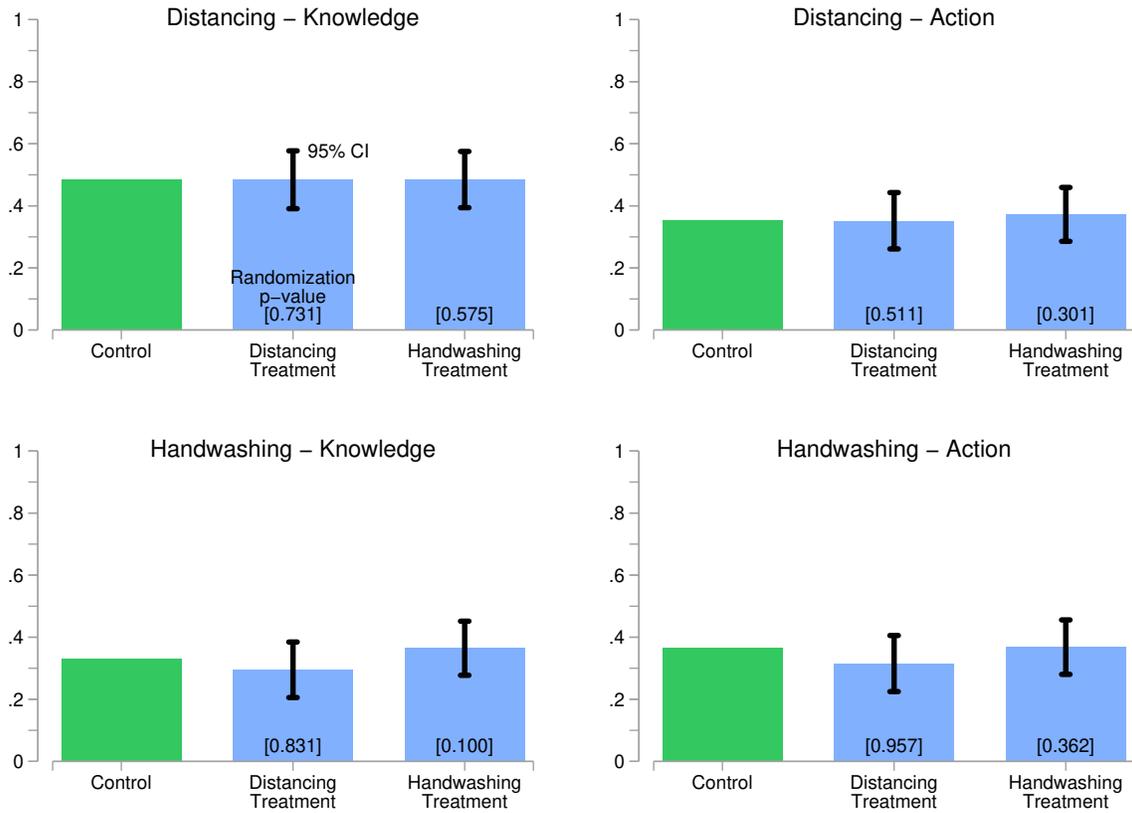

Note: Figure B.2 shows the ITT results by target behavior (social distancing and handwashing) for four main outcomes: knowledge and uptake of social distancing behavior in the upper panel and knowledge and behavior of handwashing behavior in the lower panel. Asymptotic confidence intervals bars are shown with exact p-values in square brackets below the x-axis. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. Detailed results are also shown in Table 3.

Figure B.3: ITT Results of Pooled Treatments on Perceived COVID-19 Risk
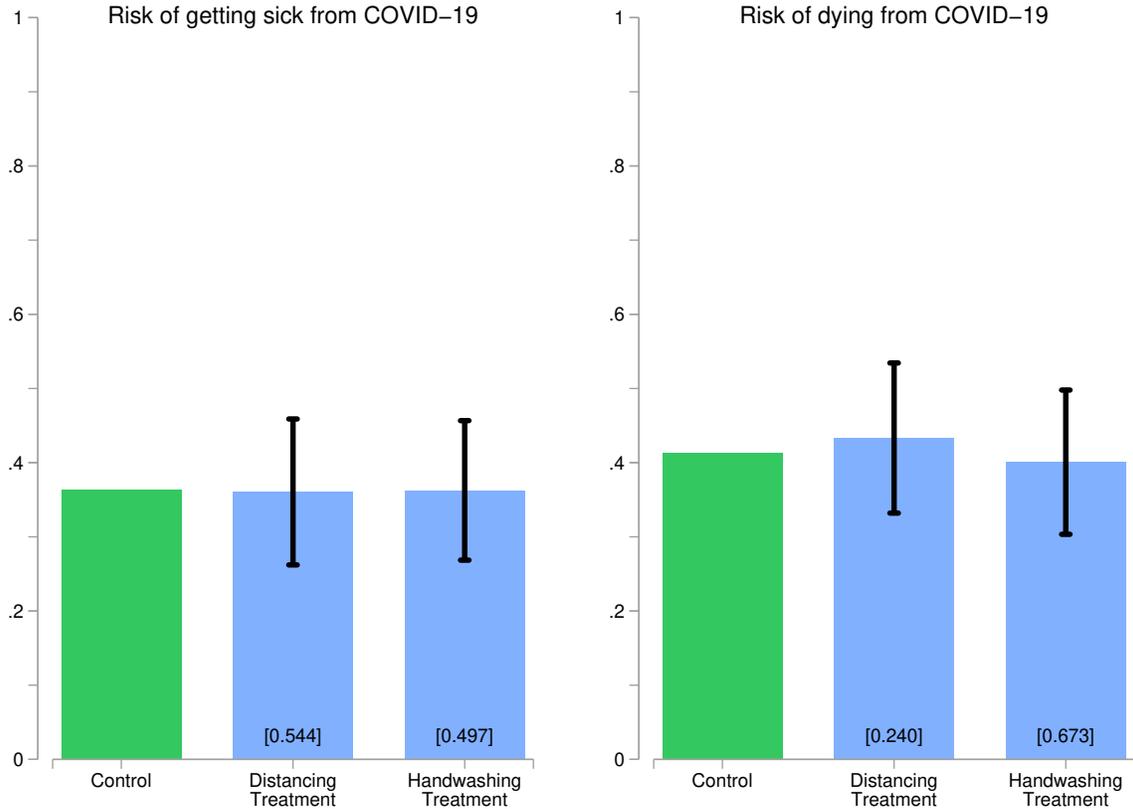

Note: Figure B.3 shows the ITT results for the pooled treatments for risk perceptions of getting sick and dying from COVID-19. Asymptotic confidence intervals bars are shown with exact p-values in square brackets below the x-axis. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes.

Figure B.4: Treatment Shares by Round
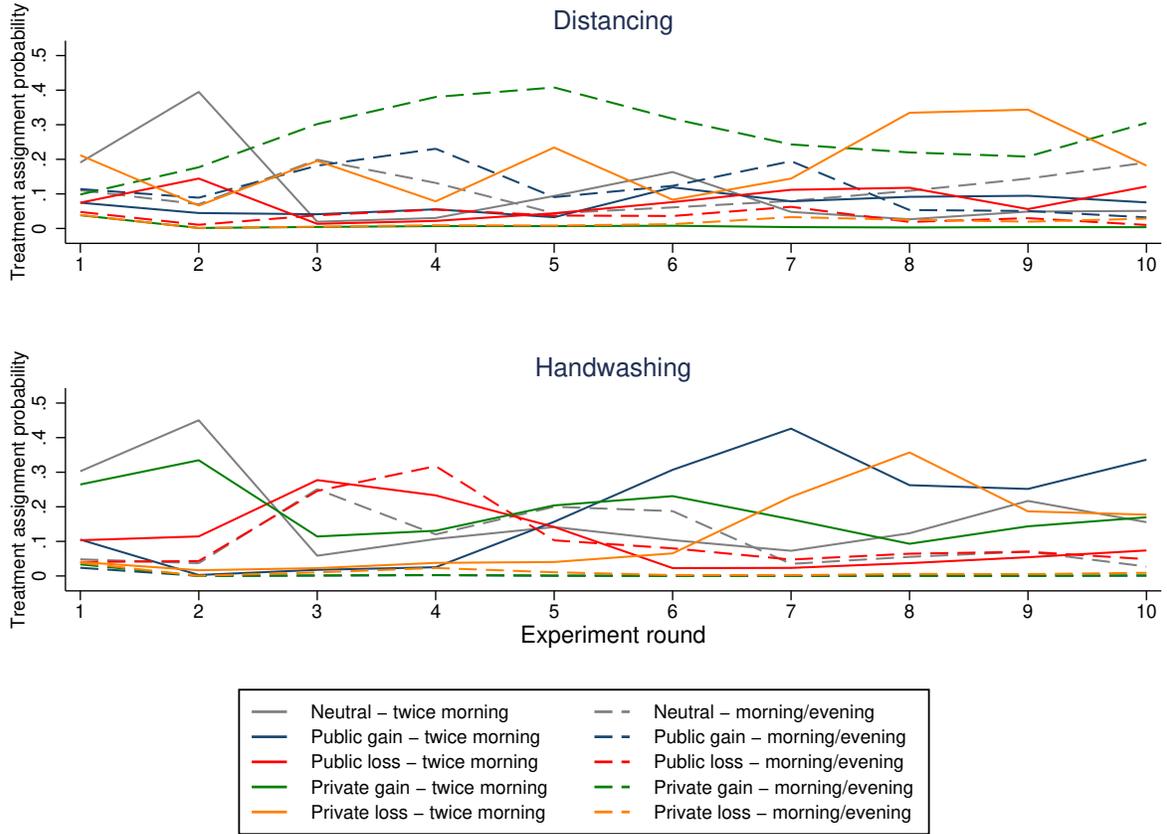

Note: Figure B.4 shows the posterior probabilities for each of the 10 treatment arms for Round 1 to 10 for distancing in Panel A and handwashing in Panel B. Round 1 comprises of first five rounds that are used as priors.

N	1,988	1,988	1,988	1,988
Control Mean	0.56	0.40	0.41	0.43

Note: Table B.1 shows two-stage least squares results using randomized treatment assignment as the instrument. Panel A reports regressions using administrative data on whether the SMS we sent was successfully delivered as the endogenous variable. Panel B reports regressions using self-reported receipt of any COVID-related message as the endogenous variable. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. Robust standard errors are in parentheses and Fisher exact p-values are in square brackets. Asymptotic p-values are denoted by: * $p<0.1$; ** $p<0.05$; *** $p<0.001$.

N	3,563	3,563	3,563	3,563
Control Mean	0.49	0.36	0.32	0.35

Note: Table B.5 shows the heterogeneity analysis for main social distancing and handwashing outcomes by study periods. The omitted group is the early period (round 1) from 16 August to 9 September 2020; the middle period includes rounds 2 through 5 from 10 September to 2 October 2020, and the late period includes rounds 6 through 10 from 3 October to 20 October 2020. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. Robust standard errors are in parentheses and Fisher exact p-values are in square brackets. Asymptotic p-values are denoted by: * p<0.1; ** p<0.05; *** p<0.001.

Table B.6: Heterogeneity Analysis by SMS Literacy

| | Distancing | | Handwashing | |
	Know	Act	Know	Act
Treatment - SD x Read SMS	-0.024	0.014	0.062	0.042
	(0.062)	(0.057)	(0.060)	(0.063)
	[0.833]	[0.736]	[0.113]	[0.206]
Treatment - HW x Read SMS	-0.103*	-0.119**	0.105*	0.089
	(0.062)	(0.059)	(0.059)	(0.062)
	[0.801]	[0.900]	[0.072]	[0.072]

N	3,106	3,106	3,106	3,106
Control Mean	0.49	0.36	0.32	0.35

Note: Table B.6 shows the heterogeneity analysis for main social distancing and handwashing outcomes by SMS literacy, defined as whether the respondent self-reported that they can read SMS in Hindi. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. Robust standard errors are in parentheses and Fisher exact p-values are in square brackets. Asymptotic p-values are denoted by: * p<0.1; ** p<0.05; *** p<0.001.

Table B.7: Treatment Effect Heterogeneity by Recall Period

N	3,563	3,563	3,563	3,563
Control Mean	0.49	0.36	0.32	0.35

Note: Table B.7 shows the heterogeneity analysis for main social distancing and handwashing outcomes by three or five day recall period. The omitted group is respondents in the three-day recall period. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. The analysis sample consists of respondents 18 years of age and above who consented to the interview and were interviewed on the fourth or sixth day after the first message was sent for the treatment group or were interviewed on the predetermined date for control group. Robust standard errors are in parentheses and Fisher exact p-values are in square brackets. Asymptotic p-values are denoted by: * p<0.1; ** p<0.05; *** p<0.001.

Table B.8: ITT Results on Additional Preventive Measures

| | Wearing Masks | | | Respiratory Hygiene | | |

	[0.534]	[0.631]	[0.361]	[0.993]	[0.896]	[0.201]
Adjusted R^2	0.10	0.08	0.11	0.01	-0.00	0.08
N	3,563	3,563	3,335	3,563	3,563	3,138
Control Mean	0.63	0.68	0.75	0.01	0.01	0.71

Note: Table B.8 shows the ITT results for additional preventive measures for pooled treatment and control group. The columns represent knowledge, unprompted and directly asked measures of wearing masks and respiratory hygiene. The regressions include fixed effects for gender, occupation, education, age, target behavior, block, day of the week, round of the experiment, enumerator, and (random) order of the knowledge and action question for the key outcomes. The analysis sample consists of respondents 18 years of age and above who consented to the interview and were interviewed three days or five days after the first message was sent for the treatment group or were interviewed on the predetermined date for control group. Robust standard errors are in parentheses and Fisher exact p-values are in square brackets. Asymptotic p-values are denoted by: * $p<0.1$; ** $p<0.05$; *** $p<0.001$.

Study design				
Setting	Bihar	West Bengal	Uttar Pradesh (& Bangladesh)	Uttar Pradesh
Intervention	Aug-Oct 2020	May 2020	Apr-May 2020	[†]
Sample size	3,563	1,883	1,680 (India)	3,991
Target behaviors	Distancing; Handwashing	Distancing; Hygiene	Distancing; Handwashing; Respiratory hygiene	Debunking fake news; COVID protocols[†]
Treatment arms	Ten per behavior[§]; Only SMS	Four[§§]; Only SMS with link to a celebrity video	Three {SMS only[§§§], Phone calls only, SMS & Phone calls}; Once a month in April and May; No pure control arm	Four[§§§§] {WhatsApp Doctor video & WhatsApp Doctor Audio}; Message debunking fake Bollywood news to control arm
Respondents	Registered at health clinic 6-12 months prior	Current and former village council members	Households previously surveyed by two local organisations	Census of households within mapped slum borders from 2017
Called after	3 and 5 days	2-14 days	1 month & 2 months	[†]
Treatment compliance	Received any COVID-related SMS; **+28.5 p.p. (1.78 times more than control) (p-value<0.05)[∓]**	Video viewing rate; **1.14%[†]**	[†]	Audio message listened (%); **-16 p.p. for low & -12 p.p. for low incentive**
First-order outcomes (respondent behavior)				
Distancing	a) Open-ended: Maintain 2 arms distance **-0.3 p.p. (p-value=0.511)[∓]** b) Prompted: Never came within 2 arms distance when meeting someone outside of household. **+0.4 p.p. (p-value=0.525)**	a) Prompted: Number of non-household people who came within 2 arms distance in the last 2 days; **-1.47 (p-value=0.206)** b) Prompted: Went outside the village (yesterday and day before yesterday); **-7.4 p.p. (p-value=0.026)**	a) Prompted: No close contact with outsiders at least on 3 separate days in the past week; **+85.3 p.p. (p-value=0.001) for calls-only; +94.8 p.p. (p-value=0.001) for calls+SMS[‡]**	a) Received visitors last week[†]; **-6 p.p.(p-value>0.1) for low; +2 p.p. (p-value>0.1) for high** b) Left slum last week[†]; **-3 p.p.(p-value>0.1) for low; -8 p.p. (p-value<0.05) for high**
Handwashing	a) Open-ended: Wash hands with water and/or soap **+0.2 p.p. (p-value=0.362)[∓]** b) Prompted: Always washed hands in the last two days **+0.7 p.p. (p-value=0.283)**	Not collected	a) Prompted: Washed hands five times in a day at least on 3 separate days in the past week; **+80.2 p.p. (p-value=0.001) for calls-only; +92.6 p.p. (p-value=0.001) for calls+SMS[‡]**	a) Number of correct hand-washing practices reported[†]; **-0.07 (p-value>0.1) for low ; +0.07 (p-value>0.1) for high**
Second-order outcomes (community behavior)				
Distancing	Prompted: Typical community member maintained 2 arms distance; **-0.7 p.p. (p-value=0.531)**	Not collected	Not collected	Not collected
Handwashing	a) Prompted: Typical community member washed hands with soap and water or used hand sanitizer; **+2.2 p.p. (p-value=0.125)**	a) Prompted: Times a typical person in the village washed hands with soap upon return (%); **+4.7 p.p. (p-value=0.044)**	Not collected	Not collected

Note: [§]5 frames × 2 delivery times. [§§]Two motivation frames (externality+internality; internality-only) crossed with two ostracism frames (no ostracism; neutral). [§§§]The SMS scripts have private gain framing. [§§§§]Cross-randomised video & audio message with high-incentive or low-incentive lottery. [†]Detailed data not available. [∓]First-stage results from Table 2; treatment effects on targeted behavior from Table 3. [‡]Using RI p-values from their table A5. Estimates are relative to SMS-only arm, and only for India sample.
